ABSTRACT

Background: In patients of knee pain diagnosis has utmost important for treatment and to avoid unnecessary surgery. MRI is a non-invasive procedure in evaluation of knee joint. So this study was planned find out the prevalence of abnormalities detected by MRI in patients of knee pain.

Methods: Fifty patient of knee pain were examined after taking permission from institutional ethics committee by using Siemens Avanto MR machine with a superconducting magnet and field strength of 1.5 tesla using dedicated knee coil (Flex), which were referred from department of Orthopedics & Rheumatology.

Results: In this present study 72% patients were males and 28% patients females and their ages ranging from (11-80) years. Knee pain was found common in age group 31-40 years. Menisci lesions (44%) were more common as compared to ligament lesions (14%) in patients of knee pain. Osteoarthritis was found in 40 % of patients of knee pain. Joint effusion and marrow edema was found with incidence of 74% and 62% respectively. 4% patients were suffering from intraarticular tumors.

Conclusions: Knee pain can occur at any stage of life due to various causative factors. MRI can demonstrate the exact nature and extent of bony as well as soft tissue abnormality. This has increase the use of MRI in evaluation of patients of knee pain.

Keywords: MRI, Knee pain, Menisci, Osteoarthritis

INTRODUCTION

Knee problems may be responsible for much of musculoskeletal disability in elderly persons. The prevalence of abnormalities increased with age, as might be expected. Knee pain is considered as most frequent symptom related to knee problems which brings patient to the hospital. Knee pain and related symptoms may come as a result of damage to one or more of the soft tissue structures that stabilize and cushion the knee joint, including the ligaments, muscles, tendons, and menisci or due to non-traumatic injury like infection, inflammation etc. 1 Presentation of knee pain in a middle-aged or older patient often leads to an x-ray of the knee but MRI is being used in clinical practice to facilitate diagnostic decisions. The potential for MRI to be more sensitive to earlier disease, detecting change, and the capacity of this technology to visualize joint structural changes beyond gross changes in bone and in the joint space, has resulted in great interest in the use of MRI for assessing diagnostic status, disease severity and monitoring progression. 2 MRI visualizes most components of the joint, including articular cartilage, menisci, intra-articular ligaments, synovium, bone marrow, subchondral cysts, and other periarticular and intra-articular lesions that are not detectable by radiography. 3 Various studies have reported structural changes in people with knee osteoarthritis by radiographic findings. Very few data are available regarding what structural changes are present in patients of knee pain and also this type of study was not
conducted in our institute. So, this study was planned to find out the prevalence of abnormalities detected by MRI in patients of knee pain which will guide the physician in making treatment strategies according to diagnosis.

METHODS

This prospective study was carried out for a period of six month after taking the permission from institutional ethics committee. A total of 50 patients referred to the department of Radio-diagnosis from department of Orthopedic and Rheumatology with complaints of knee pain were recruited. Patients’ socio-demographic data, clinical history and physical examination findings were recorded after taking informed consent to correlate the findings. The patients of knee trauma and who had no complaint of knee pain were not included in this study.

Procedure:

MRI acquisition knees were imaged by using Siemens Avanto MR machine with a superconducting magnet and field strength of 1.5 tesla using dedicated knee coil (Flex).

Each examination consisted of the following: coronal intermediate-weighted (repetition time msec/echo time msec, 2200/20) and T2- weighted (2200/80) dual spin-echo images (number of signals acquired, two; section thickness, 5 mm; intersection gap, 0.5 mm; field of view, 160 mm; acquisition matrix, 205x256; and number of sections, 20), sagittal intermediate-weighted (2200/20) and T2- weighted 4 (2200/80) dual spin-echo images (number of signals acquired, two; section thickness, 4 mm; intersection gap, 0.4 mm; field of view, 160 mm; acquisition matrix, 205x256; and number of sections, 20), sagittal three dimensional T1- weighted spoiled gradient-echo frequency-selective fat suppressed images (46/2.5; one signal acquired; flip angle, 40°; section thickness, 3 mm; section overlap, 1.5 mm; no gap; field of view, 180 mm; acquisition matrix, 205x256; and number of sections, 80), and transverse intermediate weighted (2500/7.1) and T2-weighted (2500/40) turbo spin echo fat-suppressed images (number of signals acquired, two; section thickness, 2 mm; no gap; field of view, 180 mm; acquisition matrix, 205x256; and number of sections, 62). Total acquisition time, which included the initial survey sequence, was 30 minutes. Protocol of examination was in line with European society of musculoskeletal radiology (ESSR). It starts with the patient in supine position and slightly externally rotates the foot by about 10-15 degrees to stretch the anterior cruciate ligament. Pack some cushions around the knee to help it stay motion free. A small cushion under the ankle helps to keep the leg straight. Evaluation of the knee including the patello-femoral joint, medial and lateral compartments as well as related tendons and ligaments and the popliteal fossa is performed with a high resolution proton density sequence acquired in 3 planes: Axial, Sagittal and Coronal. Evaluation of bone marrow for contusion requires a T2 fat saturation sequence in either coronal or sagittal planes. If the patient has a suspicious mass then T1 fat saturation images are helping to determine if the mass is benign or malignant and better delineate its full extent. Obtained MRI images were diagnosed by an experienced musculoskeletal radiologist for the presence of ligament injury, tear, strain and laxity, as well as menisci degeneration and tear, joint effusion, subchondral and bone marrow edema, bony contusion, bursitis, baker cyst and tumor were noted in all patients.

Statistical analysis:

Data were expressed in percentages in comparison tables and graphs. Statistical analysis was performed using Microsoft Excel Software and the standard Statistical Package for the Social Sciences version 15 for windows.

RESULTS

Total 50 patients were recruited with in a study period of six month. MRI of knee was conducted in patients who were complaining knee pain. Of these 50 patients 36 (72%) were male and 14 (28%) were female, with male to female ratio of 2.6:1. Mean age of the patients was 42 years (range 11 to 80 years). They were classified into age groups and out of these groups 12 were found to be in age group between 31-40 years. In this age group 8 were male and 4 were female patients (Table 1).

Figure 1: Demographic profile of patients including age & sex (n=50).
Instituting 2% incidence of each knee pathologies as compared to male. We could not find exact reason for that.

Joint effusion was found to be most frequent associated lesion constituting 74%. In another study joint infusion was reported in 63.8%. Higher percentage of joint effusion in our study and other study too could be due to more synovial reactions in patients of knee pain. Bone marrow edema was also found in 62% of patients of knee pain. This much high percentage of marrow edema in patients of knee pain may be due to non-specific finding which is simply fluid accumulation within the bone when there is any insult to bone. A recent systematic review reported that bone marrow lesions and effusion were associated with knee pain.10

Menisci lesions were found in 44% patients. Depending on the patient’s age, a prevalence of meniscal lesion up to 36% has been reported.11 In our study most of the menisci lesions was found in males. Similar results have reported by other studies too of higher incidence of menisci injuries in male.12,13

Grade I/II injury (signal changes) are common in our study because these are mostly occur with degeneration changes in knee joint and more common in 3rd and 4th decade14 and in our study most of the patients were in age between 31-50. A meta-analysis based on 22 studies described an overall sensitivity of 88% and specificity of 94% for detecting meniscal lesions with different grades.15 This would avoid unnecessary arthroscopic examination.1

Osteoarthritis was found in 40% of patients of knee pain with equal prevalence in both male and female. Baker’s cyst which is mostly present with osteoarthrosis patient was found in 12% in patients. Similar incidence of baker’s cyst has been reported by other study conducted by Nasir A.9 In other studies incidence of osteoarthrosis was found more in females and age above 50. The prevalence of osteoarthrosis varies greatly depending on the definition used, age, sex and geographical area studied.16,17

Difference in our study could be due to more patients in age group 21-50 years. MRI is an excellent tool for diagnosis of intraarticular tumors which in our study shows 4% incidence. MRI is accurate, noninvasive technique for evaluating the structures of the knee, marrow space, synovium and periarticular soft tissue concerning the knee.18,19

To conclude, knee pain can occur at any stage of life due to various causative factors. Most of the patients in our study found to be males. MRI gives the noninvasive diagnosis to the patients for their appropriate treatment. This has increase the use of MRI in evaluation of patients of knee pain.
