ABSTRACT

Colorectal cancer (CCR) is the third most common cancer worldwide in men and women, the second largest cause of death related to cancer, and the main cause of death in gastrointestinal cancer. The risk of developing this cancer is related to bad alimentary habits, smoking, intestinal inflammatory disease, polyps, genetic factors, and aging. Of the patients that are diagnosed with colorectal cancer 90% are older than 50, with a median age of 64 years; however, the disease is more aggressive in patients that are diagnosed at younger ages. According to the American Cancer Association, it was accounted for more than 49,700 deaths in 2015. The goal is to reduce the mortality rate with early diagnosis and treatment. Currently, the survival rate is used to predict a patient’s prognosis. The patient is considered to have a positive familial history if a first-degree relative has been diagnosed with colorectal cancer or colonic polyps before the age of 60, or also if two or more first-degree relatives have been diagnosed with cancer or polyps at any age. There are several methods for detecting colorectal cancer, such as the guaiac test, immunochromic test of stool, DNA stool test, sigmoidoscopy, colonoscopy, and barium enema. The stage in which the cancer is detected determines the prognosis, survival, and treatment of the patient. Provide a review about generalities, genetic basis, risk factors, protective factors, clinical course, diagnostic methods, therapy and survival in colorectal cancer. Conducted research from different databases such as PubMed, Medline, MedScape, on the definition, genetic factors, classification, risk factors, protective factors, diagnostic methods, epidemiology, survival and treatment of colorectal cancer. Articles from 2000 to 2017 were included using the following keywords.

Keywords: Colorectal cancer, Mortality, Epidemiology, Risk factors, Survival, Tumoral markers

INTRODUCTION

Colorectal cancer is the third most common type of cancer in oncologic pathology.¹ Currently, it is the most common malignant cancer in the gastrointestinal tract, representing 13% of all malignant tumors, and it is considered the second most common cause of death related to cancer affecting men as women in the same manner worldwide, developed and undeveloped...
countries, and it is expected to overcome the mortality rate of heart diseases in the coming years.\textsuperscript{2,4} It is a prevalent disease in those aged 65-74, with a higher prevalence in women.\textsuperscript{5} However, this pathology is diagnosed more frequently in younger patients, due to risk factors such as obesity, sedentarism, bad nutritional habits (high in fats and proteins), smoking, and the progressive aging of the population. In patients with colorectal cancer, the clinical presentation depends on the location, size, as well as the presence or absence of metastases. The clinical presentation includes symptoms such as abdominal pain, alteration of chronic bowel habits, changes in bowel movements, involuntary weight loss, nausea, vomit, malaise, anorexia, and abdominal distension.\textsuperscript{1} Distal cancers cause evident rectal bleeding in comparison to proximal cancer that can give mixed blood with stool, so it tends to occulted and in consequence, anemia may be presented as secondary sign.\textsuperscript{3} Among the unusual clinical findings we can find a peripheral lymphadenopathy especially the Virchow lymph node in the left supraclavicular space, and hepatomegaly from hepatic metastases, as well as loss of the muscular mass by cachexy.\textsuperscript{6} The carcinogenic models of the colorectal cancer models on colorectal cancer carcinogenesis include the suppressor or classic pathway, and it also include a mutator or alternative pathway. The first one is known as the pathway of chromosomal instability following a pattern of progression of adenoma present in 80% of sporadic colorectal cancer, and the second is known as the pathway of microsatellite instability where there are a wide range of mutations of genes that are present in 20% of sporadic cancer and 80% of hereditary colorectal cancer mainly by the APC 60%, p53 70%, DCC 70%, KRAS 40% y BAX 50%.\textsuperscript{7} Colorectal cancer usually starts as polyp in the intestinal mucosa, however it can also exist as an initial benign lesion called adenoma that has the ability to transform into a malignant lesion depending on its histological presentation (Table 1), and its size (Table 2), of which 60% of cases are simple adenoma, and 40% are multiple adenomas. 24% of the patients with untreated polyps will develop cancer.\textsuperscript{8} Presently, it is classified under the Astler-coller-Dukes system or TNM system established by The American Joint Committee on Cancer.\textsuperscript{9} Which represents the stage of the colorectal cancer by categories. The letter T represents the spread of propagation extension through the layers of the colonic or rectal wall, the letter N indicates if there is presence in the lymph node, and M indicates metastasis in distant organs.

**EPIDEMIOLOGY**

According to Surveillance, Epidemiology and Final Results program, in the United States there were an estimated of 132,700 new cases of colorectal cancer in 2015. This represents 8% of all the new cases of cancer, and there were an estimated of 49,700 deaths from this disease, with a mortality rate of 8.1/100.000 habitants. Which mainly affects developed regions (25.1/100.000 habitants), while the rate is significantly inferior in undeveloped regions (3.9/100.000 habitants).\textsuperscript{10} However, a gradual decline in the incidence has been observed, which reflects the increase of early detection by colonoscopy with removal of precancerous lesions in adults from 50 to 75 years of age.\textsuperscript{11,12} The use of colonoscopy increased from 19.1% to 54% in 2013. In the last report of GLOBOCAN 2012, colorectal cancer was reported as the third most common in men with 1361,000 cases representing 10% of all cancers, and it is the second most common type of cancer in women with 614, 000 cases representing 9.2% of all cancers. The occurrence for both genders oscillate in 1361,000 cases with a mortality of 694,000 (8.5% of all cancers) which is inferior with more deaths (52%) in the less developed regions of the world.\textsuperscript{13} The INEGI reported 74,685 deaths from cancer in 2010 (13% of the deaths in Mexico) from which 5.4% are cause by colorectal cancer. Colorectal cancer may be caused by sporadic or non-hereditary related to mutation errors in DNA, transcriptional silencing of suppressor tumor genes, genes involved in the control of the cellular cycle, repair, and apoptosis or genetic in origin related to mutations in suppressor gene tumors such as APC, DCC, BRAF,PIK3CA, AKT, and TP53 or the presence oncogenes as K-RAS and CTNNB1.\textsuperscript{14} Table 3) As well as chromosomal anomalies, gene mutations, epigenetic changes involving proliferation, differentiation, apoptosis and angiogenesis are also causes.\textsuperscript{15} However, it is currently considered biomarker that predicts the response to therapy through EGFR17. Sporadic colorectal cancer, by activating the oncogene K-RAS located on chromosome 12 shows mutations mainly in codon 12 and 13 (95% of the mutations) and just 5% of the mutations are in codons 61,146, 154, these mutations are mainly observed in patients with metastasis. Associations with 12 codon present mucinous type cancer mutations, while mutations in codon 13 are related to non-mucinous cancer, however this type is more aggressive with higher metastatic rate.\textsuperscript{16-18} A KRAS mutation can be considered as bad prognosis mainly in the codon 13, and is also considered to be a biomarker that predicts the response to therapy through EGFR.\textsuperscript{19} The genetic mechanism begins with an inactive mutation of the tumor suppressor gene APC, which is responsible for familial adenomatous polyposis, and approximately 85% of colorectal cancer without hereditary relationship. Some of the adenocarcinomas develop after a mutational activation of the B-catenin (CTNNB1) regulated by APC, or by a second mechanism initiated by the inactivation of a family of tumor suppressor genes involved in the repair of the DNA. These genes are known as MMR genes or Mismatch including the human homolog mutS (MSH2), the human homolog 1 Mutl, (MLH1), and the possemitic segregation gene increased type 2 (PMS2) including both in hereditary afflictions as well as sporadic colorectal cancer. Mutations always occur in specific ways, first those that affect the APC gene followed by those that affect the RAS gene.\textsuperscript{19} Changes in TP5, the suppressor tumor gene is affected in 50% of the cases and it tend to appear more towards at the end of the sequence.\textsuperscript{20} In the
Somatic alterations, it can affect the glicoproteic signal pathway WNT/B-catenin that is associated with cellular proliferation, tissue homeostasis, and its mutation is associated to human diseases such as congenital malformations, cancer, osteoporosis, and is found in 95% of patients with colorectal cancer.21,22 The rs59336 allele located in the intron of the TBX3 gen of the WTN/B catenin pathway has been associated with an increase risk in developing colorectal cancer.23

However, alterations in genes such as SMAD7 have been associated with affecting the progression of colorectal cancer, and there are three known variants of the SMAD7 gene (rs44939827, rs12953717, and rs4464248) in the 8q21 chromosome that increase the risk of colorectal cancer.24,25 However, these are not the only genetic errors that can influence the risk of colorectal cancer.26 Currently, metastases protective genes have been identified, such as KISS1, which connects to the KISS receptor. This is essential for the suppression of metastasis, and the survival rate significantly improves to high levels of KISS1 and KISS1R.27 Genes that protect against metastasis have been identified, such as KISS1, which connects to the KISS receptor. This is essential for the suppression of metastasis, and the survival rate significantly improves with high levels of KISS1.

**RISK FACTORS**

Among the risk factors related to developing colorectal cancer, which is estimated that 35% can be explained by hereditary factors. Nevertheless, family history has great relevance for risk of colorectal cancer, as well as colon or rectal cancer, hereditary diseases such as familial adenomatous polyposis, hereditary colon cancer without polyposis which is known as Lynch syndrome.28 It is associated with gene mutations implicated in the pathway
of repair of bad DNA coupling/mating (MMR, mismatch repair) specifically MLH1, MSHS2, MSH6, and PMS2. The mutations in MLH1 and MLH2 are majority about 90% of the mutations found in families of hereditary colon cancer with or without polyposis. However APC germline online mutations, repair MTHYU, SMAD4, BMPR (Alq3), STK11, represent less than 5% of all cases of colorectal cancer.29 It is estimated that these genetic syndromes represent about 10% of all cases of colorectal cancer; however about 25% of cases the familial history contributes to an increased risk of developing colorectal cancer in the absence of these genetic syndromes 30. Factors such as history of ulcerative colitis, Chron’s disease, personal history of polyposis, colon, rectal, ovarian, endometrium, breast cancer, and diabetes mellitus are related to a 30-50% greater risk of developing colorectal cancer, and about 75% of the malignant tumors of the colon and rectum are presented without related any of these risk factors; The relationship between hyperplastic polyposis and cancer is controversial. Adenomatous polyps are common in adults which are over 50 years old, but most polyps will not turn malignant. Its histology and size determine its clinical relevance. Risk factors for malignancy in hyperplastic polyps include polyp size equal to or above 10mm, or dysplasia, right colon localization. A focus of an adenoma within the polyp (mixed polyp hyperplastic-adenomatous); in which the presence of more than 20 hyperplastic polyps in the colon, and familial history of colon cancer. In a period of a clear evolution between 10-15 years with define stages, initiating as a minor dysplasia that progresses depending on the genetic modifications to moderate or severe. The dissemination pathways is determined by either hematic or lymphatic, which defines the speed of growth and the time of evolution of the disease, however there have been reported cases of implantation by surgical manipulation after a laparoscopic colectomy.3 The adenomatous polyps are common in adults over 50, but most of the polyps will not turn malignant. The histology and size will determine its clinical relevance. The risk factors for a hyperplastic polyp to turn malignant includes size equal to or above to 10mm, dysplasia, location in the right colon, a focus of adenoma inside another polyp (mixed hyperplastic-adenomatous polyp), presence of more than 20 hyperplastic polyps in the colon, and familial history. It develops with a clear evolution between 10-15 years starting as mild dysplasia that progresses depending on the genetic modifications to moderate or severe. The dissemination pathways are either hematic or lymphatic, and defines the growing rate and the time of progression of the disease; however cases have been reported of surgical implantation following a laparoscopic colectomy.

**PROTECTING FACTORS**

The ingestion of non-steroidal anti-inflammatory drugs reduce the risk of colorectal cancer, however the molecular basis have demonstrated, which regulates the overexpression of the receptor of the epidermal growth Factor (EGFR), which is overexpressed in the 80% of the cases colorectal cancer, as an early event in colorectal tumorigenesis. The overexpression of the cyclooxygenase 2 (COX-2) triggers the activation of the transcription factor of the c-Jun dependent protein activator 1 (AP-1) that binds to the promoter of EGFR; therefore selective COX-2 inhibitors can be used as quintomipreventive activity against colorectal cancer.31 However, it has been demonstrated that dietary high fiber ingestion is a factor of prevention against colorectal cancer and other tumors, as well as high consumption of fruits and vegetables, however, no association has been found for colorectal cancer, or association for separate ingestion of fruits and vegetables.32 The variety in consumption was not associated with a decrease in the risk of colon cancer, but if there is an increased with a high in the variety in fruit consumption reflected in a 41% of higher risk for those who ingest more than 8 different fruits every two weeks.35

**DIAGNOSTIC METHODS**

Current screening methods targeting moderate risk populations (Table 4) aged 50 or more include the fecal occult blood test (TSOH) with the high sensibility based on the Guaiac or immunologic test (TSOH) with an annual periodicity; sigmoidoscopy every 5 years with TSOH every 3 years, or colonoscopy every 10 years.34 Diagnostic methods are largely related to the overlife of a patient with colorectal cancer, however some methods such as fecal occult blood can present in false positive results that coincide in high consumption of red meat, vegetables, and fruits that may contain peroxidase versus persons with no bleeding condition that ingest vitamin C may result in a false positive test.3 Despite this, technology has enable the development of techniques such as PCR, which allows to identify biological genetic markers by doing its specific test, and its purpose is to identify mutations in specific gene related to colorectal cancer. Currently for the identification of colon and colorectal cancer concentrations of the homebox duodenal pancreatic transcription factor (PDX-1) in the development and proliferation of pancreas whose levels
increase mainly in malignant cancer that of the pancreas, breast, colon, prostate, renal and metastasis versus low levels in primary tumors or null levels in healthy colon tissue, therefore it is considered biomarker in colorectal cancer.35-37

The hypoalbuminemia would constitute a simple and significant marker of bad prognosis, other tests such as sigmoidoscopy which present improvements day by day where 65-75% of adenomatous polyps, and 40%-65% of the colorectal cancers are within reach of sigmoidoscopy; however about 50% of the advance adenomas (>1cm) and proximal colon cancer were undetectable in this method.3

Although it is the only technique that is of scrutiny, diagnosis and therapeutic management of the colon is a procedure that implies a higher cost, risk and discomfort for the patient compared to other tests.38 Notwithstanding, the overexpression of proteins and genetic factors, they can currently be considered as markers of patient bad prognosis factors such as high levels of mRNA and paxilne in colorectal cancer related to the histological tumor grade, tumor sizes, clinical TNM stage and remote metastases where it is shown that the prognosis of the patients with high level of paxilne was unfavorable versus low expressions of paxilne as well as shows a Pre-treatment hypoalbuminemia (<3.5 g/dl ) that is related independently with a lower survival after resection. Both globally and in colorectal cancer stage II plus hypoalbuminemia, so to confirm these results the hypoalbuminemia would constitute a simple and significant marker of bad prognosis, available from the time of diagnosis.39,40

SURVIVAL TO 5 YEARS

Survival or survivorship is a value that predicts a patient’s prognosis; to 5 years refers to the percentage in which a patient lives at least five years after the diagnosis of cancer; taking in to account the type and stage of the cancer, as well as particular factors in the treatment administrated (the genomic modifications of the cancer cells as well as the individual and their biological variability). The 5-year and 10-year relative survival rates for persons with colorectal cancer are 65% and 58%, respectively.41 It is to say those patients who survive more than 5 years, after the diagnosis of colorectal cancer without taking into account age, histological type, or stage of the disease. In a study conducted by Wulaningsih et al. in patients diagnosed with cancer, it shows an inversely proportional relation to the levels of LDH (enzyme lactate dehydrogenase) and the survival is to say they were compared with the pre-diagnostic LDH levels, increasing the risk of death from prostate, lung, gastrointestinal, and colorectal cancers, while high intervals near the diagnostic period are related with the overall and specific mortality of the cancer.42

The survival of patients diagnosed with colon, rectal and colorectal cancer is variable according to the type and stage. Patients which got stage IIIA or IIIB cancer have a better survival than those patients whose got stage II B cancer, patients so much so that survival in rectal cancer was better for some patients with stage III cancers than for some in stage II cancers. However in the study of Dobras et al; It shows a worse survival for patients in stage III with mutation in KRAS that in those patients with KRAS type wild IE without mutation in the oncogene, another of the genes related to survival is the expression of the gene KISS1 and KISSR which shows a direct proportional correlation with the survival of colorectal to greater expression of the same survivability increases 44.3 and 39.3 to 45.8 and 42.2% respectively. with the Gene expression the survival rate increases from 44.3 and 39.3% to a 73.7 and 67.9% respectively. Patients with low levels of KISS 1 showed in patients a remote metastasis; statistically significant., therefore KISS 1 could be a promising prognostic and therapeutic marker in colorectal cancer.43 As a leading cause of death in these patients approximately 50-60% of the patients diagnosed will develop metastasis.44 In general the five-years lifespan varies from 65% in the United States, 55% in other developed countries, 14% in Africa, and 39% in developing countries.41 Survival ranges are significantly different by stage, 90% for localized disease, 68% for regional disease with lymphatic affection, and 10% for disseminated disease related to the early detection unlike other types of cancer in which the size of the tumor does not affect the prognosis of the disease; however the increase in the mortality rate is justified in the increase of the life expectancy in the population, in the relation of the increase of genetic alterations due to greater susceptibility to carcinogenic, immunosuppression and comorbidity of the patients which explains the greatest risk of developing colorectal cancer.43 Mortality rates are variable in terms of gender, with a very slight prevalence of female sex, in colon cancer (51 vs 49%), and male sex in colorectal cancer (53 vs 46), mainly by liver metastases as a leading cause of death in these patients.42 Approximately 50-60% of the patients diagnosed will develop metastasis.44 Survivors may also suffer from bladder dys-function, sexual dysfunction, and negative body image.45,46

DIAGNOSIS BY LOCATION

Most tumors are localized in the rectum (37%), and sigmoidal (31%), being less frequent in ascending colon (9%), cecum (8%), descending colon (5%), transverse colon (4%), hepatic angle (4%), and splenic angle (2%).43 About 65% of colon cancers are distal to the splenic angle and highly detectable by sigmoidoscopy versus 35% of colon cancers that are proximal to sigmoidal and not detectable by flex sigmoidoscopy.3

The recurrence of the disease is associated with the elevation of serum values of carcinoembryonic antigen (ACE) in the 60-70% of the cases, and is considered value increased the concentration of ACE highet 5mg/l related to an unfavorable prognosis to the patient; however its value maintains significance mainly in stadium TNM II.27

Likewise, the SEPT9 protein has been implicated as a biomarker for more than 10 years, it has been shown as a precise, reliable, fast, and convenient method for colorectal cancer.59

TREATMENT

Stage 0 cancer can be treated by removing cancer cells by colonoscopy. For stage I, II and III Cancer, it is necessary to perform surgery using radical colectomy of the segment involved with margins > 5 cm., lymphadenectomy to the root of the nutrient vessel (minimum 12N), suspicious ganglion biopsy outside the resection field. It has been demonstrated that the laparoscopic approach is as safe as the traditional open approach for colorectal cancer.38 In patients with metastases in distal organs the addition of irinotecan to Fluouracil and Leucovorin was demonstrated prolongs survival in patients and was considered the new first-line standard therapy for this disease in patients with stage III cancer receive complementary chemotherapy after surgery for 6 to 8 months, improving symptoms and prolonging survival in people with stage IV cancer primarily.59 The 5-Fluoracil continues to be the cytostatic mostly used in the treatment of colon cancer, those who make use of it or at least approach the fulfillment of the therapeutic standard, achieve better percentages of survival. Currently, the role of an antibody variant called Bevacizumab (Avastin) approved by the US Food and Drug Administration (FDA) has been studied by lowering vascular endothelial growth factor (VEGF), the main angiogenesis regulator, produced by normal and neoplastic cells 50 Preclinical trials have shown that a human monoclonal antibody against VEGF can inhibit the growth of xenografts of human tumors.30,51

In addition, to its direct antiangiogenic effects bevacizumab can improve direct antiangiogenic and may also improve the delivery of chemotherapy by altering the tumor vasculature and lowering elevated interstitial pressure in the tumors.52 The addition to bevacizumab to IFL improved the global survival; compared to only IFL the IFL regime plus bevacizumab increases progression-free survival from a median of 6.2 months to 10.6 months, the overall response rate of 34.8 to 44.8% and the average response duration of 7.1 months to 10.4 months by means of the primary (bevacizumab)) mechanism of tumor growth inhibition rather than cireduction.53 However the use of IFL with or without bavacizumab increase in the incidence of thrombosis, hemorrhage, proteinuria, and hypertension.54,55 Radiotherapy is usually used in combination with chemotherapy for stage III rectal cancer patients, indicated in those cases where the margin of surgical resection is compromised, as in the case of adherence or infiltration to neighboring organs or the retroperitoneal space. However patients with stage IV colorectal cancer that has disseminated to the liver, it should be taken into account, the various therapeutic approaches targeted specifically to the affected organs including ablation, chemotherapy or radiotherapy, cryotherapy or surgery. Patients with metastases present active the KRAS oncogene showing resistance to treatment with anti-EGFR antibodies, so you will have to perform an evaluation of the KRAS (mutated or normal) for anti-EGFR therapy: approximately 30-050% of patients with colorectal cancer are known with mutated KRAS, which could indicate that > 50% of patients would respond to anti-EGFR therapy, however, only 40-60% of these patients will respond, patients with mutated KRAS denote a decrease in survival compared to patients with wild type KRAS without activation of the oncogene.56,57

HEPATIC METASTASIS FROM COLORECTAL CANCER

The most common site of metastases in patients with colorectal cancer is the liver, due to its anatomical location with respect to its portal circulation. The liver is the most common site of metastasis in patients with colorectal cancer because of its anatomical location with respect to its portal circulation. Approximately 14-18% of patients with colorectal cancer have been detected with this type of cancer from the first medical consultation and 10-25% at the time of primary colorectal cancer resection.58 The poor prognostic factors remain the presence of metastases, recurrent disease and the advancement of local tumors. Despite advances in chemotherapy, surgery remains the treatment of choice, overcoming other treatments such as cryosurgery or radiofrequency ablation. Surgical treatment of isolated metastasis is a well-established treatment for selected patients and achieves a 5-year survival of between 39 and 58%. It has been reported that the 5-year survival rate following the surgical procedure for liver metastasis is 25-44%, with an intraoperative mortality of 0-6.6%. Modern surgical techniques performed at major hepatobiliary centers have shown that 70% of hepatectomy can be achieved with a mortality of less than 5%. With the help of Liver resections, the 5-year survival rate, even in those with a positive margin of less than 1 mm, could be increased to 25%. In cases where there are sufficient surgical margins (< 1 mm), 5-year survival rates could be up to 40%. It is vital to know the predisposing factors, the mechanisms, the diagnostic methods, the treatment of liver metastases, due to their anatomical situation in the abdominal cavity. The adoption of more and better programs in the health system is extremely important, with objectives focused on prevention, early diagnosis and adequate treatment that help the survival and prognosis of patients.59-61
