ABSTRACT

Background: Stroke is a disease of paramount public health significance. The role of plasma fibrinogen in determining incidence and severity of stroke has been postulated time and again. Present study was undertaken to determine the correlation between mean plasma fibrinogen level and infarct volume on CT scan in patients with acute stroke.

Methods: Present prospective observational study of two years duration at our tertiary care government centre entailed enrollment and radiological assessment (CT scan/MRI) of 50 consecutive patients with first-ever stroke admitted within 24 h after stroke onset along with measurement of their plasma fibrinogen levels at admission.

Results: Thirty (60%) cases reported ischemic stroke while haemorrhagic stroke was observed in 20 (40%) cases. The mean fibrinogen levels in ischemic (584±62mg/dl) and haemorrhagic stroke (52±28mg/dl) were found to be significantly higher (p<0.05) than normal range of (200-400mg/dl). The mean infarct volume in patients with ischemic stroke was 62.79±9.51cm³ while mean plasma fibrinogen level was 584±62mg/dl. There was significant correlation between infarct volume and fibrinogen levels (r coefficient =0.61; p<0.05). The fibrinogen levels in patients who died was insignificantly higher as compared to patients who survived.

Conclusions: We report significantly higher than normal mean fibrinogen levels in ischemic and haemorrhagic stroke with the correlation between infarct volume and fibrinogen levels being significant in ischemic stroke. Limited mortality numbers probably didn’t allow the present study to reach the level of significance. Similar studies with larger sample size are recommended.

Keywords: Hemorrhagic stroke, Ischemic stroke, Plasma fibrinogen level

INTRODUCTION

Stroke is a major global public health problem. According to the Global Burden of Diseases (GBD) study in 1990, stroke was the second leading cause of death worldwide.¹ With the rising proportion of mortality, stroke still remains the second leading cause of death worldwide.²

In India, the cumulative incidence of stroke was recently reported higher than those of high-income countries, ranging from 105 to 152/100,000 persons per year.³ Thus stroke poses a serious public health concern for India.

Thus, it becomes imperative to look for factors contributing to the increased chances and severity of stroke. Risk factors include diabetes, hypertension, smoking and hyperlipidemia and these have been linked to abnormalities of coagulation.⁴ A number of biological markers such as leptin, high sensitivity C-reactive protein (hs-CRP), insulin, cortisol, fibrinogen, protein C, protein S, Von Willebr and factor, D-dimer, Antithrombin III and MMP-9 have been evaluated for their prognostic values and their relationship with lesion volume in stroke patients.⁵ ⁶ Fibrinogen is a plasma glycoprotein that is converted by thrombin into fibrin during blood clot formation. The role of hypercoagulability and of plasma
fibrinogen, the central protein of the coagulation system, in
this complex scenario has been suspected for many
years, and has recently been documented by experimental
and clinical evidence.7,8 In a developing country with
limited health care facilities and with neuroimaging being
inaccessible in certain areas, plasma fibrinogen can easily
be made available and is postulated to be effective
parameter for assessing the severity and prognosis in
stroke cases.

The present study was undertaken to determine the
correlation between mean plasma fibrinogen level and
infarct volume on CT scan among patients with acute
stroke.

METHODS

It was hospital based prospective observational study.

Study was carried out at Medicine wards, tertiary care
government institute. Period of the Study was from
November 2014 to November 2016 (Two years).

Sample size was calculated with 95% confidence in
interval estimation, 15% anticipated range from previous
similar studies and 10% absolute error of margin. The
minimum sample size was derived to be 50.

Selection criteria

- Consecutive patients with first-ever stroke admitted
  within 24 h after stroke onset
- Patients with past history of stroke, active infections
  or malignancy, renal, cardiac or liver disease, pregnant
  women, patients with transient ischemic attack, CNS
  tumours, recent head injury and patients/relatives not willing to participate in the
  study were excluded.

Operational definitions

Stroke

Rapidly developing clinical signs of focal (or global)
disturbance of cerebral function, with symptoms lasting
24 hours or longer or leading to death, with no apparent
cause other than of vascular origin.9 Diagnostic criteria
for acute stroke would consist of sudden onset of focal/
global neurologic deficit with objective confirmation of
arterial-distribution ischemia/hemorrhage by computed
tomography (CT) or magnetic resonance imaging (MRI).

Hyperfibrinogenemia

Plasma fibrinogen concentration >3.5g/L (as determined
by modified Clauss method).10,11

Those willing to participate in study were enrolled as per
mentioned selection criteria after obtaining a written
informed consent either from patient or 1st degree
relative. Ethical clearance was obtained from Institutional
Ethics Committee prior to commencement of the study.

Fifty consecutive patients with first-ever stroke coming to
Medicine OPD or emergency medical services of our
tertiary care centre and admitted within 24 h after stroke
onset were studied with detailed history taking,
comprehensive clinical examination. All the participants
were subjected to radiological examination (CT scan or
MRI) for confirmation, as relevant. Routine
haematological and other investigations were conducted
in all the participants. Blood sample for plasma
fibrinogen concentration was withdrawn at the time of
admission after stabilization of the patient. Clinical
course of patients during the admission as well as the
outcomes were assessed by relevant parameters.

Data was analysed using SPSS (version 20) and
unpaired t-test and chi-square tests were applied, as relevant. ‘P’
value less than 0.05 was considered significant.

RESULTS

A total of 50 patients of stroke were enrolled and studied. Thirty (60%) cases reported ischemic stroke while
hemorrhagic stroke was observed in 20 (40%) cases.
Thirteen out of 50 (26%) patients were in the age group
of 31-40 years; with age distribution of rest of the
participants being relatively evenly distributed. Males
(29, 58%) outnumbered females (21, 42%).

Right sided hemiparesis was observed in 27 cases (54%)
while left sided hemiparesis was found in 21 cases (42%).
Headache (29, 58%) was the commonest symptom
followed by vomiting (26, 52%) and altered sensorium
(20, 40%) in all types of stroke patients. Atherosclerosis
was observed to be the most common cause of ischemic
stroke (70%) followed with cardiogenic embolism
(26.7%) and sickle cell disease (3.3%); whereas
hypertension was found present in majority of
hemorrhagic stroke patients (12, 60%) along with other
conditions (AV malformation, Moya Moya disease,
Warfarin toxicity and preeclampsia in 2 patients each).

Assessment of risk factors revealed that out of 4
peripartum females, 3 suffered ischemic stroke and 1 had
hemorrhagic stroke. Similar were the findings for
patients on oral contraceptive pills (OCP). Obesity and
abnormal lipid profile were found to be more associated
with occurrence of ischemic stroke. Rheumatic valvular
heart disease (RVHD), smoking, alcohol consumption
and tobacco use was found to be similar across all groups
(Table 1).

The mean fibrinogen levels in ischemic (584±62mg/dl)
and hemorrhagic stroke (52±28mg/dl) were found to be
significantly higher (p<0.05) than normal range of (200-
400 mg/dl). The mean infarct volume in patients
with Ischemic Stroke was 62.79±e9.51cm³ while mean plasma
fibrinogen level was 584±62mg/dl. It was observed that
fibrinogen level increased with increasing infarct volume. There was significant correlation between infarct volume in patients with Ischemic Stroke and fibrinogen levels (r coefficient =0.61; p<0.05).

The mean infarct volume in patients with Haemorrhagic Stroke was 60.58±10.52cm³ while mean plasma fibrinogen level was 552±28mg/dl. It was observed that fibrinogen level did not increase with increasing infarct volume and there was no significant correlation between infarct volume in patients with Haemorrhagic Stroke and fibrinogen levels (r coefficient =0.3; p>0.05) (Table 2).

Seven and five patients with ischemic and haemorrhagic stroke respectively died in the present study. There was no significant association between mortality and occurrence of specific type of stroke. The fibrinogen levels in patients who died was higher as compared to patients who survived. Although fibrinogen levels were higher in patients who died, the association of fibrinogen levels with mortality was not significant (p>0.05) (Table 3).

DISCUSSION

Present study entailed assessment of 50 consecutive patients with first-ever stroke admitted within 24 h after stroke onset and trying to establish correlation between their plasma fibrinogen levels and various acute stroke parameters.

At the outset, as far as subtyping the stroke from prognostic point of view is concerned, it is believed that comparisons between hemorrhagic (HS) and ischemic stroke (IS) are hampered by the disproportionate distribution of the 2 types of stroke, with IS being 10-times more frequent than HS in Western countries. Even in large stroke cohorts absolute numbers of HS are low, rendering statistical validation of differences between the 2 types of stroke difficult. So, any difference observed between the two stroke variants needs to be looked at with this caveat in mind.
In the present study, 40% patients reported embolic stroke while thrombotic and haemorrhagic stroke were observed in 30% of patients each. A study by Nayak SD et al observed thrombotic and haemorrhagic stroke to be occurring in 24% and 25% patients respectively.16 While in the study of Andersen KK et al, 35491 (89.9%) had IS whereas 3993 (10.1%) had HS.17 Twenty six percent patients were in the age group of 31-40 years. 26 out of 30 (52%) patients reported with stroke were females and 24 (48%) were male. This is similar to the study of Azam R et al.18

Atherosclerosis (ATH) was the most common cause of ischemic stroke (70%) followed with cardiogenic embolism (26.7%) and sickle cell disease (3.3%). This is concordant to the findings of Tripathi M. et al.19 Smoking has previously been observed to be significantly associated with ischemic stroke.20,21 This is similar to the finding in present study that reports significant difference in occurrence of ischemic stroke in patients with history of smoking as compared to haemorrhagic stroke.

The mean fibrinogen levels in ischemic and haemorrhagic stroke was found to be significantly higher than normal, which correlates well with the findings of Narayanaswamy M et al.22 The mean infarct volume in patients with Ischemic Stroke was 62.79±9.51 cm³ while mean plasma fibrinogen level was 584±62 mg/dl. It was observed that fibrinogen level increased with increasing infarct volume. There was significant correlation between infarct volume and fibrinogen levels (r coefficient =0.61; p<0.05); whereas in a study done by Azam R et al, the mean infarct volume was 64.32±1.15 cm³ while mean plasma fibrinogen level was 4.78±1.43 mg/dl, correlation coefficient r value was 0.5 while p value was 0.02.18 The mean haemorrhage volume in patients with Haemorrhagic Stroke was 60.58±10.52 cm³ while mean plasma fibrinogen level was 52.2±28 mg/dl. It was observed that fibrinogen level did not increase with increasing haemorrhage volume. There was no significant correlation between haemorrhage volume and fibrinogen levels (r coefficient =0.3; p>0.05).

Seven and five patients with ischemic and haemorrhagic stroke respectively died in present study. No significant association was observed between mortality and occurrence of specific type of stroke. Andersen KK et al, had observed that; compared with ischemic strokes, hemorrhagic stroke was associated with an overall higher mortality risk (HR, 1.564; 95% CI, 1.441-1.696).17 The increased risk was, however, time-dependent; initially, risk was 4-fold, after 1 week it was 2.5-fold, and after 3 weeks it was 1.5-fold. After 3 months stroke type did not correlate to mortality. It was observed in both the groups that the fibrinogen levels in patients who died was higher as compared to patients who survived. Although fibrinogen levels were higher in patients who died, the association of fibrinogen levels with mortality was not significant. This was also corroborative of the finding of Andersen KK et al.17

CONCLUSION

In conclusion, we report significantly higher than normal mean fibrinogen levels in ischemic and haemorrhagic stroke and fibrinogen levels increased with increasing infarct volume and the correlation between infarct volume and fibrinogen levels being significant in ischemic stroke. In both the groups, the fibrinogen levels in patients who died was insignificantly higher as compared to patients who survived. Limited mortality numbers probably didn’t allow the observations of present study to reach the level of significance, which prompts us to recommend similar study with higher numbers.
